Advance Python Assignment

Topic-2: Reading Data from Keyboard

Q1. Using the input() function to read user input from the keyboard.

Ans.
The input() function in Python is used to take data from the user through the keyboard. It allows the program to interact with the user by accepting values at runtime. By default, the input received is always in string format, so we need to convert it into other data types when required. This function is very useful in creating dynamic programs where the user can enter different values each time. It makes the program flexible and user-friendly. Proper use of input() helps in building simple interactive programs.

Example:
```
name = input("Enter your name: ")
print("Hello", name)
```

Q2. Converting user input into different data types in Python.

Ans.
In Python, the data received from the input() function is always in string format. Sometimes we need to perform operations like addition or calculations, so we must convert the input into other data types such as int or float. This is done using type conversion functions like int() and float(). Converting input data helps in performing mathematical operations correctly. It is important to use proper conversion based on the requirement of the program.

Example:
```
age = int(input("Enter your age: "))
salary = float(input("Enter your salary: "))

print("Age:", age)
print("Salary:", salary)
```
